EL EFECTO DEL GASTO SOCIAL EN LA DISTRIBUCIÓN DEL INGRESO: UN ANÁLISIS PARA ECONOMÍAS LATINOAMERICANAS

Resumen

Usando un panel de datos desde 1980 al año 2000, este artículo analiza los determinantes de desigualdad en los ingresos para los países latinoamericanos, con especial atención a variables del gasto en educación, salud y seguridad social. Con respecto a investigaciones anteriores, este estudio resuelve problemas de endogeneidad de las variables del gasto social en la ecuación de desigualdad de ingresos, usando métodos 2SLS y GMM. Si bien el gasto público afecta a la desigualdad, el aumento de la desigualdad puede estar relacionado con cambios sociales, económicos y políticos que también pueden afectar el gasto del gobierno. Por lo tanto, el gasto social es potencialmente endógeno en la regresión de la desigualdad y, a menos que esta fuente de endogeneidad se corrila, los parámetros estimados no serán consistentes. Una vez se controla esta endogeneidad, los resultados muestran que el gasto en educación y salud tienen un efecto negativo sobre la desigualdad de ingresos, mientras que el gasto en seguridad social no tiene efecto sobre la desigualdad. También se encuentra que los modelos que no tienen en cuenta la endogeneidad del gasto social, tienden a sobreestimar los efectos del gasto en educación y salud.

SOCIAL SPENDING EFFECT ON INCOME INEQUALITY: AN ANALYSIS FOR LATIN AMERICAN ECONOMIES

Abstract

This paper analyses the determinants of income inequality in Latin American countries using a panel dataset from 1980 to 2000, focusing on topics such as education, health, and social security expenditures. Previous research was used to solve the endogeneity of the social spending variables in the income inequality equation. In addition to this, this study undertakes 2SLS and GMM methods in order to control the correlation of some of the regressors with the disturbance term. While government expenditure affects inequality, an increase in inequality may be related to social, economic and political changes that can also affect government expenditures. Therefore, social spending is potentially endogenous in the inequality regression and, unless this source of endogeneity is accounted for, the estimated parameters will be not consistent. Results show that social spending variables are endogenous with income inequality index. Once endogeneity is controlled, education and health expenditures have a negative effect on income inequality, while social security expenditures have no effect on income inequality. Findings also evidence that models, which do not take into account endogeneity of social spending variables, overestimate the effects of education and health spending.

Key words

Social spending, income distribution, GMM, endogeneity.

O EFEITO DO GASTO SOCIAL NA DISTRIBUIÇÃO DA RENDA: UMA ANÁLISE PARA ECONOMIAS LATINO-AMERICANAS

Resumo

Usando um painel de dados desde 1980 ao ano 2000, este artigo analisa os determinantes de desigualdade nos rendimentos para os países Latinoamericanos com especial atenção a variáveis do gasto em educação, saúde e segurança social. Com respeito a investigações anteriores, este estudo resolve problemas de endogeneidade das variáveis o gasto social na equação de desigualdade de rendimentos usando métodos 2SLS e GMM. Conquanto o gasto público afeta à desigualdade, o aumento da desigualdade pode estar relacionado com mudanças sociais, econômicas e políticas que também pode afetar o gasto do governo. Portanto, o gasto social é potencialmente endógeno na regressão da desigualdade e, a não ser que esta fonte de endogeneidade se corrija, os parâmetros estimados não serão consistentes. Uma vez se controla por esta endogeneidade, os resultados mostram que o gasto em educação e saúde têm um efeito negativo sobre a desigualdade de rendimentos, enquanto o gasto em seguranca social não tem efeito sobre a desigualdade. Também me encontra que os modelos que não têm em conta a endogeneidade do gasto social tendem a sobrestimar os efeitos do gasto em educação e saúde.

Introduction

here is strong evidence that Latin America and the Caribbean form the region with the highest average level of inequality and particularly with the highest concentration of income at the very top. More specifically, according to the World Bank (2004), the top 10 percent of income earners among Latin Americans earn 48% of total income, while the poorest tenth earn just 1.6%. The equivalent figures for high-income countries are 29.1% and 2.5%. Using the Gini Index of inequality in the distribution of income and consumption, the Economic Commission for Latin America and the Caribbean (ECLAC), found that Latin America and the Caribbean, from the 1970s through the 1990s, measured nearly 10 points more unequal than Asia, 17.5 points more unequal than the 30 countries in the Organization for Economic Cooperation and Development (OECD), and 20.4 points more unequal than Eastern Europe.

The income distribution in Latin America has varied little over recent decades, despite big changes in economic policies. Londoño and Székely (1998) using data from household surveys showed that income inequality across Latin America as a whole declined slightly in the 1970s, increased during the 1980s due the debt-crisis and a sharp increase of inflation in a number of countries, and showed no clear pattern in the 1990s.

The concern about income distribution in Latin America is increasing, and it is not clear if the economic model now being followed is making matters better or worse, at least in terms of income inequality (Morley, 2001). On one hand, some reforms such as opening national borders, decentralization efforts, privatization of state enterprises, and shifting away from progressive income tax systems to broad-based taxes on consumption might be expected to shift the distribution of income even more toward the rich. On the other hand, the considerable increases in social spending and broad coverage of public education in most

of Latin American countries might be an effective instrument of distribution of income toward the poor.

Using a panel dataset from 1980 to 2000 this paper analyzes the determinants of income inequality in Latin American countries with special attention paid to education, health, and social security expenditures. I built on previous research by solving for the endogeneity of the social spending variables in the income inequality equation. This study undertakes 2SLS and GMM models in order to control for the correlation of some of the regressors with the disturbance term. While government expenditure affects inequality by redistribution, an increase in inequality is related to social, economic and political changes that can also affect government expenditures. That is, as social policies might be thought of as a mechanism to reduce income inequality, they might also be determined by inequality levels. This raises the problem of reverse causality (Niehues, 2010). Therefore, social spending is potentially endogenous in the inequality regression and, unless this source of endogeneity is accounted for, the estimated parameters may be inconsistent. In addition, most of the variables that determine income inequality are also determinants of social expenditure.

Results show that social spending variables are endogenous with income inequality index. Once endogeneity is controlled for, education and health expenditures have a negative effect on income inequality, and social security expenditures have no effect on income inequality. Results also show that models that don't take into account endogeneity of the social spending variables overestimate the effects of education and health spending.

The remainder of this paper is organized as follows. I first summarize previous research concerning income inequality in Latin American countries. I then discuss the literature concerning the determinants of income inequality, paying special attention to social spending factors. The data and econometric model are described in the third part of the paper, with an emphasis on endogeneity problems of social

spending. Results and conclusions are presented in parts four and five respectively.

Inequality in Latin American
Countries

Why is Latin America so unequal? Lloyd-Sherlock's (2000), Morley (2001), the World Bank (De Ferranti et al., 2004) offer the most comprehensive analysis of the determinants of unequal distribution of income in Latin American countries. Surprisingly, to the best of my knowledge, no cross-country econometric models have addressed the problem of endogeneity of the right hand side variables of the income inequality equation for Latin American countries.

Lloyd-Sherlock's gave a descriptive analysis of the level of inequality in Latin America. He emphasizes that while the overall levels of social spending are much higher than in most of Asia, the patterns of government budget allocations are very different in the two regions: education is the dominant sector in Asia, while social security dominates in Latin America. In addition, low income groups in Latin America are often excluded from many areas of public welfare because of the poor administrative capacity of the governments, and there are severe problems of access and quality for important social services in Latin America such as education and public healthcare.

According to the World Bank, inequality in Latin America is mainly due to the interlocking effects of four things: access to education is unequal; the earnings of educated people are disproportionately high; the poor have more children with whom they must share their income; and targeting of public spending is ineffective. De Ferranti et al. (2004) evaluate the effect an extensive range of variables including economic, demographic, and political determinants on income equality, but a limitation of this important work is that they do not use present regression analysis. They contend that the correlation

across countries between educational and income inequality is clearly positive and significant.

Morley identifies three central factors that help explain Latin America's high level of inequality. First, Latin America has a highly unequal distribution of education and the highest skill differentials for university graduates in the world. That is, Latin America let most of its young cohorts drop out after primary school, using the money saved at the secondary school level to expand university education. Since it is mainly the poor who drop out of school, educational inequality rose in the 1990s in every country in the region, except Brazil. Second, the combination of a highly skewed distribution of land and an increase in the growth rate of the labor force in recent decades has driven down the relative wage of the unskilled. Rural-urban migration in the twentieth century reduced the pressure in the countryside, but at the cost of transferring inequality and low wages for the unskilled to the urban sector. The combination of an unequal distribution of land, rising population growth rates and a failure of the education system to absorb and educate the young has left the region with an oversupply of poorly educated workers. Third, the unusually large gap between the average incomes of the rich and those further down the income pyramid adds to inequality. Morley used data for sixteen countries in Latin America from 1960 to 1997, including national income, inflation, education, economic reform indices, and land distribution as determinants of income distribution. He used two different samples, one for levels and the other for changes in the distribution, and estimated both fixed and random effects model. He found that income is significant and has the inverted U-shape that Kuznets predicted, but that this relation has been shifting in a regressive direction over time. He concludes that giving new entrants to the labor force and more education at any level is progressive, but countries will get a much bigger reduction in inequality if they start at the bottom, universalizing the coverage of primary education and then broadening the coverage of secondary and university education. Finally, he found that tax reform is unambiguously regressive, and opening up

the capital account is unambiguously progressive. However, this study does not include social expenditures, a measure of democratization, and effect of openness to international trade, which are presumably important policies that may influence income inequality.

Huber et al (2005) examines the determinants of inequality using a panel dataset for 18 Latin American and Caribbean countries for the period 1970 to 1995. They use the Gini Index of income equality as the dependent variable for multiple regressions. They find that health and education spending has a negative impact on inequality, meaning that such spending reduces income inequality, while social security and welfare spending (transfers, primarily pensions) has a strong positive impact on inequality. They use robust-cluster standard errors in order to control for correlation among errors of observations for the same country. The problem with this method is that it requires the errors to be uncorrelated between countries, which could be violated if unmeasured factors affect the dependent variable in all units at the same point in time.

Lusting et al (2012) estimates the impact of taxes and social spending on inequality and poverty in Argentina, Bolivia, Brazil, Mexico, Peru and Uruguay. They found that in-kind transfers in education and health reduce inequality in all countries by considerably more than cash transfers. This study relies microdata obtained from household surveys, and apply a standard benefit-tax incidence analysis to estimate the effect of direct and indirect taxes, cash and in-kind transfers and indirect subsidies on inequality and poverty. However, thay only have data for one year, limiting the results.

The reverse causality of social expenditure on income distribution has been recently addressed by other authors. Schwabish (2008) is concerned with how earnings inequality has affected spending at the state level in the United States between 1977 and 2005. In general, he shows that increases in inequality in both the upper- and lower-tail of the earnings distribution serve to increase social spending. For US, he found that a one percent increase in overall inequality, as

measured by the Gini coefficient, is associated with a rise in social spending of about 0.255 percent, or \$680 per person. On the other hand, Schwabish et. al (2006) find that the inequality between the middle classes and the poor (as measured by the 50/10 percentile ratio) has a small, positive impact in social spending; but inequality between the ends of the distribution and middle class (measured by the 90/50 percentile ratio) has a large and negative impact on social spending. This study control for different measure of trust in societies.

Other theoretical and empirical work has also establish the double correlation between social transfers and redistribution by the paradox of redistribution. Sinn (1995) states that welfare programs, such as social security, are expected to have a positive effect on pre-government income inequality, but can also induce increasing investment in risky assets. Therefore, paradoxically, more redistribution may result in more post-tax inequality. Korpi and Palme (1998) found an inverse relationship at the country level between social transfer targeting and redistribution. They claim, "the more we target benefits at the poor, the less likely we are to reduce poverty and inequality". However, recent literature (Marx et al, 2013) state that this no longer holds in a broad set of empirical specifications. They find that targeting tends to be associated with higher levels of redistribution, especially when overall effort in terms of spending is high.

Finally, Niehues (2010) address the endogeneity of social expenditure variables on the income inequality equation. He applied a GMM estimator using a dynamic panel approach with European countries between 1993 and 2007. He found that more social spending in general policies effectively reduces inequality levels in European countries, while more targeted benefits do not significantly reduce income inequality. Although, he focused on welfare programs rather than social expenditure, he provides a theoretical framework that explains how social transfers could discourage recipients from taking part in the labor market at all, which in turn also increases pregovernment income inequality. In Latin American countries, this could be true in special for health expenditures.

Literature Review: Determinants of Inequality

There is a substantial literature that examines demographic and economic determinants of income inequality. Economic development, globalization, economic freedom, government expenditure, education inequality, and democracy are variables that have been regularly associated with inequality. The association between economic development and income inequality was first analyzed by Kuznets (1955) who found an upside down U-shaped curve. That is, increased economic development is associated with increased inequality at lower levels of development, but then shifts at some point beyond which increased development is associated with decreasing inequality. Therefore, we would expect a positive relationship between economic development and inequality since most of the Latin American countries are at low or medium levels of industrialization and only few have passed the highest point of the curve.

It is of interest to see whether various indicators of globalization have a direct impact on inequality. **Openness** by both capital and trade flows have been examined in the empirical literature for their effects on income inequality but with inconclusive results. Barro (2000) finds that in developing countries openness to trade, non-protectionist policies, and smaller government are associated with greater income inequality. In contrast, Dollar and Kraay (2002) find evidence that free trade and open economic policies lead to increased equality in a sample of eighty countries that covers over 40 decades. Milanovic (2002) finds a more complex relationship whereby openness in low-income countries tends to benefit only the rich, but openness in higherincome countries largely benefits the poor and middle class.

Alderson and Neilsen (1999) consider the role of foreign investment in income inequality using an unbalanced crossnational data set for 1967 through 1994. They improve upon previous studies by estimating random-effects regression models that control for unmeasured country specific

heterogeneity to investigate the effects of foreign capital penetration on inequality (measured as the Gini coefficient) against the background of an internal-developmental model of inequality. They conclude that the relationship between income inequality and investment dependence should be revised in light of an investment-development path relating the inflow and outflow of foreign capital to economic development.

Rudra (2004) also investigates the relationship between openness, government expenditures, and income distribution using a panel data set for 35 less developed countries from 1972-1996. She finds that openness has a much more severe impact on inequality in developing nations. Only education spending helps mitigate the adverse effect of openness on income inequality in poorer countries, while spending on healthcare, social security and welfare do not. She also finds that income distribution tends to be much more sensitive to trade flows in developing countries than in more industrialized nations. Her results indicate that increasing amounts of trade worsen income distribution in the developing world if the government does not engage in certain types of pro-poor social spending to alleviate it. Capital flows, in contrast to trade flows, have a minimal effect on inequality in both sets of countries.

Population growth and population under 15 years of age are generally expected to push up the level of inequality. The oversupply of unskilled young workers depresses lower incomes and increase wage differentials (Alderson and Nielsen, 1999). Aged population is also expected to have a positive impact on inequality. The argument is that higher elderly population suggests lower productivity, lower savings rates, and smaller intergenerational transfer of income (Deaton and Paxson, 1997).

Urbanization can also affect income distribution. Growth of the urban population contributes to a higher middle class, and more employment (Boschi, 1987). Similarly, the larger the proportion of the labor force in agriculture, the higher

the degree of inequality. As the movement of the labor force shifts from agriculture to the urban sector, low-paid rural jobs become less important and inequality is expected to decrease. Deininger and Squire (1996) showed that inequality in the rural samples in Latin America is generally higher.

It is expected that **democratic** nations will exhibit a more favorable distribution of income. Some studies contend that more authoritarian regimes cause income distribution to be skewed because income will be concentrated in the hands of a few elites who hold political power (Muller, 1988; Burkhart, 1997; and Huber et al., 2005). Muller and Buckhard measure the presence of immediate presence of democracy in the year of observation. Instead, Huber et al. measure the strength of the democratic tradition and find a positive correlation with income inequality, meaning that the stronger the democratic tradition of country the more unequal the distribution of income.

Research also examines the link between income inequality and various measures of education. Most studies find a negative relationship between income inequality and a country's average or median educational attainment. Enrollments also are examined for their effects on income inequality. Barro (2000) finds a negative relationship between primary and secondary school enrollments and income inequality but a positive relationship between higher education enrollments and income inequality. The relationship between secondary enrollments and income inequality may be thought of as one which is inherently connected to development. That is, an increase in the supply of educated workers tends to diminish the gap in wages and, thereby, decreases income inequality. Morley (2001) finds that in Latin America the spread of education over the last 30 years coincides with a trend towards increasing income inequality. This is a direct result of the tendency to support only primary education rather than both primary and secondary education. In contrast, Shanahan (1994) finds no

relationship between an expanded educational system and a country's degree of income inequality.

The direct relationship between **educational inequality** (unequal distribution of human capital) and income inequality yields mixed results. Checchi (2000) concludes that when the distribution of educational attainment is accounted for the relationship between attainment and income inequality is actually U-shaped. De Gregorio and Lee (2002) find a positive relationship between the two; whereas, O'Neil (1995) finds a negative relationship: "incomes have diverged despite substantial convergence in education levels".

The relationship between inequality and overall government spending as well as government spending for particular services have been studied but the results are not consistent across these various studies. Moene and Wallerstein (2001) use data for 18 OECD countries between 1980 and 1990. Controlling the unemployment rate, voter turnout, rightist government, percent elderly and a lagged measure of expenditure, higher inequality is associated with lower social spending. However, Moene and Wallerstein omit differences across nations that could be correlated with both inequality and social spending, which could lead to seriously biased estimates of the effect of inequality. Sylwester (2002) considers how education expenditures are associated with subsequent changes in income inequality within a cross-section of countries. After dividing the sample into OECD and lessdeveloped-country subsamples, he finds that education expenditures are more strongly associated with falling income inequality in the former group. Rudra (2004) finds that while all categories of social spending help reduce income inequality in richer countries, the effects of social spending are much less favorable in LDCs. In LDCs, only spending on education reduces income inequality in the face of globalization. Rudra contends that education spending mitigates the adverse effects on openness in inequality.

In Latin America the evidence for the distributive impact of social spending is more mixed and tends to vary for

1 Social security expenditures tend to favor the formal labor sector and benefits are unequally distributed since they are tied with earnings.

different kinds of expenditures. Ferrati et al. (2004) indicates that education spending is progressive, health spending is slightly progressive or neutral, and that social security spending tends to be regressive. Deininger and Squire (1998) find that educational expenditures are positively associated with inequality, though causal relationships are ambiguous. Finally, Huber et al (2005) find that health and education spending has a negative impact on inequality, while social security and welfare spending has a strong positive impact on inequality.

$$\begin{aligned} Gini_{it} &= \sum \alpha_o + \sum \beta_j EconomicDevelopment_{it-1} + \sum \beta_k \overline{SocialSpending}_{it-1} + \sum \beta_l Openess_{it-1} + \\ &\sum \beta_m Education_{it-1} + \sum \beta_n X_{it-1} + \sum \delta_p decade_t + \sum \lambda_q sample_t + \mu_{it} \end{aligned}$$

Mod∈l

The general regression model for the level of income inequality can be written as follows:

Where:

 ${\bf a_o}$ is a vector of intercepts that capture unobservable country specific effects such as: historical experiences, initial conditions, and cultural differences.

 $\mathbf{b}_{\mathbf{j}}$ is a vector of slope coefficients for per capita GDP and per capita GDP square.

 \boldsymbol{b}_k is a vector of slope coefficients for per capita education, health and social security spending.

 \boldsymbol{b}_{l} is a vector of slope coefficients for trade and foreign direct investment

 \boldsymbol{b}_{m} is a vector of slope coefficients for gross enrollment ratio for primary, secondary and tertiary education.

 \mathbf{X}_{it} is a vector of observable country characteristics which are hypothesized to have an effect on the income distribution

such as population > 65 years old, democracy, urbanization, and level of decentralization.

 $\mathbf{d_p}$ is a vector of intercepts that capture time specific effects. $\mathbf{l_q}$ is a vector of dummies which reflect the variance in methodology to estimate the Gini index (e.g., urban versus national surveys, household income versus income per capita, expenditure versus income).

 \mathbf{m}_{it} is the error term which is assumed to be normally distributed .

The model is estimated by the fixed effects method using time dummies and a decade dummy variable to control for economic shocks or other time specific effects. The decade dummy variable is particularly important to check the effects of the 1980s crisis on the model, particularly since social spending fell during that decade. Decade dummies are preferred to year dummies due to the small size of the sample.² Fixed effects are useful for controlling for idiosyncratic differences across countries with regard to inequality. Country specific effects are important in this model

2 Regressions are also estimated using year dummy variables however the results don't change significantively.

since most of the variation occur across units rather than over time. The intercept of the fixed effects model estimates the differences in inequality between countries and time dummy variables capture variation within them through time.

In order to control for the causal relationship between social spending and income distribution, a 2SLS estimation procedure is used for the empirical analysis. Higher order moments of the spending variables and lagged variables are used as instruments for social expenditure variables. This method was proposed by Lewbel (2012), which serves to identify structural parameters in regression models with endogenous or mismeasured regressors in the absence of traditional identifying information, such as external instruments or repeated measurements. In that context, the approach is similar to the dynamic panel data estimators of Arellano and Bond (1991), as those estimators customarily make use of appropriate lagged values of endogenous regressors to identify the model.

Aditionally, a first differenced GMM panel data model is estimated because of its potential for obtaining consistent parameter estimates even in the presence of measurement error and endogenous right-hand side variable. Different assumptions about the presence of measurement errors and the endogeneity of right-hand-side variables will have implications for the validity of specific instruments. These assumptions can be tested in the GMM framework by the use of the Sargan test of over-identifying restrictions.

Table 3 presents the descriptive statistics for the determinants of social spending and inequality. Results of the social spending regression are presented in Table 4 for education, health and social security expenditures respectively. Table 5 presents the results for the determinants of inequality controlling for the potential endogeneity of the social

spending variables. Two alternative models are estimated using different econometric methods: fixed effects and fist differenced GMM model. Model 1 includes only socioeconomic³ and social spending variables. Model 2 represents socioeconomic, social spending, and educational variables. Model 3 is a combined model utilizing socioeconomic, social spending, educational variables and sample dummy variables.

Data

Using data from the World Income Inequality Database (WIID), the World Bank's World Development Indicators (WDI), International Monetary Fund's Government Finance Statistics (GFS), and the Polity IV dataset measure of democracy, this paper estimates the effects government spending, and selected educational and economic factors on income inequality. I use an unbalanced panel data set with 200 observations from 19 Latin American and Caribbean countries, specifically Argentina, Bolivia, Brazil, Chile, Colombia, Costa Rica, Dominican Republic, Ecuador, El Salvador, Guatemala, Jamaica, Mexico, Nicaragua, Panama, Paraguay, Peru, Uruguay, and Venezuela. The data span the period 1980 to 2000. With only a few exceptions, the observations are annual.

The dependent variable for this study is *income inequality*, measured using the Gini coefficient, which was obtained from the World Income Inequality Database (WIID). This data set includes the often used GINI data developed by Deininger and Squire (1996). Using their data has the following advantages: it is possible to compare results with prior research, has an intuitive interpretation⁴, and satisfies particular standards of quality. Only "high quality" observations are included in the

- 2 Regressions are also estimated using year dummy variables however the results don't change significantively.
- 3 Socioeconomic variables include economic development, openness and specific socioeconomic country characteristics.
- 4 The Gini coefficient has an intuitive interpretation: is a measure between 0 and 100, where 0 means perfect equality and 100 represent perfect inequality in household and individual based distribution of incomes.

Table 1. Summary of Gini coefficients

Country	Mean	Std. Dev.	Freq.	Min	Max
Argentina	44.53	3.00	16	39.8	49.5
Bolivia	54.70	3.53	10	49.4	60.2

Total	50.48	6.49	200	31	65.5

analysis. The drawback of using this data is that there are several missing values which result in an unbalanced dataset. There are a minimum of 2 and a maximum of 20 observations per country. I use yearly data in order to make use of every observation and to capture the effects of annual changes. Table 1 presents summary statistics for the Gini coefficients of Latin American countries in the sample.

Independent Variables

I use the natural log of GDP per capita (in constant 2000 US dollars) as the variable for *economic development*, which is commonly used in the literature. This variable was retrieved from the World Bank's World Development Indicators (WDI). As is also common in the literature, I include the squared value of this term as another variable, to allow for the Kuznet's hypothesis of a non-linear relationship.

Two variables encompass the measures of globalization in this study: capital and trade flows. These variables were retrieved from the WDI. Trade openness is measured by exports and imports as a percentage of GDP. Foreign direct investment (FDI) measures net inflows of investment as a percentage of GDP. We can expect that the openness coefficients will be positive and significant.

Per capita spending on health, education, social security and welfare are reported in the International Monetary Fund's Government Finance Statistics (GFS). An alternative measure of percentage of a country's public expenditures for each category above is used in order to test for robustness of the spending effect on inequality. One limitation of the expenditure data is it is not disaggregated for different levels of education or health. Therefore, it is not straightforward to predict a sign for this variable. We would expect a negative overall effect of

 Table 2. Means of Social Spending per capita for Latin American countries

Country	Social Spending	Education Spending	Health Spending	Social Security Spending
Argentina	17.81	3.71	4.19	7.28
Bolivia	7.59	3.79	2.48	2.00

government expenditure on inequality index. Table 2 presents the means for the spending variables by country.

I also include the following educational variables: gross elementary, secondary and tertiary enrollment ratio. According to the World Bank this variable is defined as "the ratio of total enrollment, regardless of age, to the population of the age group that officially corresponds to the level of education shown". These variables were also obtained from the WDI. We expect education attainment to reduce inequality and promote economic growth. In Latin America, primary education has been universalized since 1970 for primary education, but not for secondary education, and so large proportion of students drop out at that point. This explains the fact that educational attainment has coincided with increasing inequality in Latin American countries in the last 30 years. Consequently, we would expect a negative coefficient for higher education but a positive coefficient for primary education.

The Polity IV data set is used to derive both measures. Democracy is scored on a scale of 0 to 10 (10 being the highest) and rated by: (1) regulation, competitiveness, and openness of executive recruitment, (2) executive constraints, and (3) regulation and competitiveness of political competition. For this analysis I apply both measures of democracy. Following Segura and Kaufman (2004), a democracy dummy variable is constructed by coding any country scoring at least 7 as democratic; otherwise, they are coded authoritarian. We expect the countries with the longer democratic traditions to have less income inequality.

A measure of urbanization, the percentage of the population which live in urban areas, is included in the model as determinant of inequality. We expect that more urban countries have less income inequality. I finally test for the effect of the percentage of the population which is 65 and older for the model, predicting social security and welfare spending and of the percentage of the population which is under 15 years

of age for the model predicting spending on health and education.

Other variables are included in the empirical model such as inflation, unemployment, debt, deficit, among others in order to control for economic effects. However, the estimates for these variables are either insignificant and with very small coefficients in the inequality equation. Therefore, these

variables are dropped from the analysis.

Results

The general regression model fits the data well, explaining anywhere from 45% to 67% of the total variance in the Gini coefficient over time and across countries. In addition, the

estimates and significance of the coefficient appear to be robust and consistent across different specifications.

Descriptive results from this research support the assertions that there has been a general trend toward increased withincountry inequality in recent history (Graph 1). For instance,

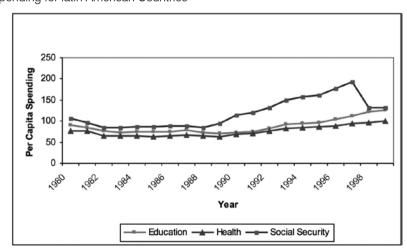

the average within-country Gini index increased from 46.83 in 1983 to 54.80 in 1999. Descriptive statistics also reveal that there has been a trend toward greater social spending per capita in Latin American countries in the last two decades (Graph 2). Likewise, primary and secondary enrollments have increased over the decades being studied. The average

Graph 1. Gini index of income inequality for latin American Countries

Source: Author's estimation

Graph 2. Social Spending for latin American Countries

Source: Author's estimation

gross enrollment ratio increased from 52.25 in 1980, to 56.48 in 1990, to 71.67 in 2000.

Statistic analysis suggests a negative correlation between social spending and inequality, and a positive correlation between education enrollment and inequality. However, these correlations don't control for other factors that affect income inequality, so multiple regressions analysis yield more reliable effects of social spending on income inequality.

The fixed effects model provides the preferred estimates among the different econometric methods used for the analysis. First differenced GMM estimators are very limited due to the small sample that results once the dependent variable and right hand side variables are lagged⁵.

Social spending estimates are consistent for every model specification. Education and health spending estimates are positive, statistically significant, and almost equal. On average estimates indicate that an increase of one dollar in education spending reduces index inequality by about 0.6 percentage points, while an increase of one dollar in health spending decreases index inequality by about 0.4 percentage points. Social security spending seems to have no effect on income inequality. These results provide evidence that education and health spending are slightly progressive in income. This result by itself is not surprising. In fact, this is the same outcome of most of the studies that have analyzed the effect of social spending in income inequality. However, estimates from this study differ from previous ones in that the size of the effect is lower when we control for endogeneity of the social spending variables. I consider this statement the most important result of this study.

Economic development variables support for Kuznets' hypothesis: increased economic development tends to increase inequality before a threshold of income is reached. After this point the curve turns, so increased development

lessens inequality. The estimated parameters are almost equal for model 1 and model 2. In model 3, the estimated parameters for log of GDP per capita and its square hold the same signs as in model 1 and model 2, but they are not statistically significant at conventional levels. That is, controlling for the methodology and data used to estimate the Gini index reduces the effect of income per capita in income inequality. This result makes sense since income is in fact the most important variable to estimate the Gini index. That is, the significative effect of income per capital on Gini index is due to the fact that income per capita is used to estimate the index and not because the data support Kuznets' hypothesis. Trade seems to have a negative effect in income inequality, while foreign direct investment has a positive but not statistically significant effect. The negative effect of trade is significant at conventional levels and support the hypothesis that education spending helps mitigate the adverse effect of openness on income inequality in poorer countries, while social security and welfare do not.

Urbanization has a positive and significant effect on income inequality. This effect goes against the hypothesis that growth of the urban population contributes to a higher middle class, more employment, and less inequality. It would be interesting to find some explanation for this atypical effect. One hypothesis is that the process of urbanization on most Latin American countries could be a consequence of total absence of government, bad economic conditions, and violence in rural areas, rather than a consequence of better economic opportunities of large cities. That is, forced displacement from rural to urban areas could generate higher levels of inequality in urban areas.

Aged population estimates are negative but not statistically significant on all specifications. Unless we expect a positive coefficient for aged population, a positive coefficient makes sense given that Latin America countries are all developing countries with a large young population. Hence, the adverse

5 A small sample results because I am using unbalanced panel dataset, and there are a lot of missing values in the dependent variable.

effect of aged population in income distribution could not be applicable for these countries.

When educational variables are considered in Model 2 and 3, secondary and tertiary enrollments are significant at conventional levels, yet they have opposite effects on income inequality. Secondary enrollments have a negative effect on income distribution while tertiary enrollments have a positive effect. These findings support the premise that secondary enrollments increase the supply of educated workers and, thereby, decrease income inequality. In contrast, higher education increases income inequality since it creates a large gap in wages, and it is available only for a small percentage of the young population.

The dummy variables for the variance in methodologies are quite large. In the case of the income vs. expenditure dummy, our results indicate that the income based studies result in a Gini index that is 11points higher than is the case of expenditure based studies. The national dummy suggests that a Gini index based on a national sample is 6points higher than one based on urban sample. Finally, the household income dummy suggests that a Gini index based on a household income is 2 points lower than one based on income per capita. Democracy doesn't have consistent estimates among specifications, yet it is not statistically significant.

Conclusions

Many problems arrive when cross country sample are used to analyze determinants of income inequality. First, as Huber argued, common estimators of inequality such a Gini coefficient don't capture the positive benefits of education and health spending in the short run. In general, the effect that health and education spending has on improving human capital in the bottom half of the income distribution would appear only with a considerable lag. Second, there is causality for some of the variables that determine income

inequality such as social expenditure and income. Third, cross-country data scarcity would not allow to control for most of the endogeneity problems that arrive for this specific model.

This analysis contributes to the literature on the determinants of cross-country income inequality and offers new insights into the complex relationships between social spending and income inequality. Estimated parameters are consistent and unbiased when we control for the endogeneity of social spending in the income inequality equation. Results show that models that don't take into account endogeneity of the social spending variables overestimate the effects of education and health spending.

From a policy perspective, this research leads valuable insights on the distributive effects of expenditures on education and health. On one hand, I found evidence that education and health expenditures reduce income inequality in developing countries, being more effective education than health spending. On the other hand, I found that analogous estimates of the effect of social expenditures on income inequality were overestimated because inappropriate econometric methods have been used in previous studies.

Nevertheless, results from this study are not conclusive. The overall estimates of social spending found in this study are limited in the sense that the effect of social expenditures on income distribution depend on the allocation of these expenditures. That is, spending on primary education will be distributive and spending on university education regressive, so the greater the share of education spending going to primary education, the more progressive the overall impact. The same argument holds for different assignments of health expenditures. Problem is that there is not data that disaggregate for lower levels of expenditures. Therefore, the overall estimate could be misleading.

Even with the limitations of the data, this research is still able to produce results that are valuable on their own, and which also serve as the foundation for more robust studies in the future.
